A diffusion-reaction model for the growth of bacterial colonies is presented. The often observed cooperative behavior developed by bacteria which increases their motility in adverse growth conditions is here introduced as a nonlinear diffusion term. The presence of this mechanism depends on a response which can present hysteresis. By changing only the concentrations of agar and initial nutrient, numerical integration of the proposed model reproduces the different patterns shown by *Bacillus subtilis* OG-01.

I. INTRODUCTION

Some kinds of bacterial colonies present interesting structures during their growth [1–11]. Depending on the bacterial species and the culture conditions, colonies can exhibit a great diversity of forms. In general, the complexity of the growth pattern increases as the environmental conditions become less favorable. Bacteria respond to adverse growth conditions by developing sophisticated strategies and higher micro-level organization in order to cooperate more efficiently. Examples of these strategies are: the differentiation into longer-motile bacteria, the production of extracellular wetting fluid, the secretion of surfactants which change the surface tension or the chemotactic response to chemical agents produced by bacteria [1–8]. The experiments are usually made in a petri dish, which contains a solution of nutrient and agar. A drop of bacterial solution is then inoculated in the center of the dish. The growth conditions are controlled by the initial concentration of the medium components. The agar concentration determines the consistency of the medium, which becomes harder as the amount of agar increases, and the nutrient concentration controls the bacterial reproduction. Depending on these two factors, the colony grows at a higher or lower rate, developing different kinds of patterns.

In particular, colonies of the bacterium *Bacillus subtilis* OG-01 present a rich variety of structures [8–11]. Fig. 1 shows the morphological diagram obtained by Matsushita and co-workers [10]. They classified the colony patterns into five types, from A to E, whose main features can be summarized as follows. If the medium is very hard, i.e., with a high concentration of agar, bacteria can hardly move and the colony essentially grows due to the consumption of nutrient and subsequent reproduction. If the level of nutrient is also low (region *A*), the growth is controlled by the diffusion of the nutrient up to the bacteria placed at the interface. The colony develops a ramified structure very similar to the patterns obtained with the diffusion-limited aggregation model (DLA) [9,12]. It takes approximately one month to cover the dish. If the initial agar concentration remains high and the nutrient concentration is increased, the growth is faster than in region *A*. The branches grow thicker until they fuse into a dense disk with rough interface (region *B*), similar to the patterns obtained with an Eden model [13]. This structure needs 5-7 days to cover the disk. When the level of agar is decreased, which produces a medium a little softer than in region B, and the level of nutrient remains high, the colony forms concentric rings (region *C*). This region is characterized by periodic dynamics: for 2-3 hours the colony expands while the bacteria move actively ("migration phase") and then they almost stop for 2-3 hours ("consolidation phase"), during which the colony does not grow appreciably and the bacterial density increases due to reproduction. The crossover between the two phases is sharp. The periodic cycles of subsequent migration and consolidation phases create the pattern of concentric rings [8,11]. Accurate measurements show that in the growth phase there is a high concentration of longer and more motile bacteria, as a consequence of a differentiation process [8]. When a high level of nutrient is maintained, and the agar concentration is decreased further, the colony spreads over the agar plate, and after less than 8 hours homogeneous disk of low bacterial density is formed covering all the dish (region *D*). In this thin surface, bacteria are always short and can move easily by swimming. By decreasing the nutrient concentrations for a semi-solid medium, the colony develops a densely branched pattern (region *E*) similar to the dense branching morphology (DBM) found in other systems [14]. The ratio of the width of the branches to the gap between them is constant over the whole colony. The colony grows quite fast, showing its main activity at the tips of the fingers, and covering the dish in less than 24 hours. The dynamics is related to both the consumption of nutrients and the bacterial motility. In general, when environmental conditions are adverse (low nutrient or hard surface), a higher level of cooperation is observed.

The existence of a cooperative behavior seems to be determinant in the formation of the rings patterns of re-

gion C. The same kind of concentric rings has been found in experiments with other bacterial species. In the case of the bacterium *Proteus mirabilis*, the migration phases clearly involve the movement of differentiated swarmer bacteria (elongated and hyperflagellated) [5–7]. Similar ring patterns have also been observed in other non-living systems, like the Liesegang rings produced by precipitation in the wake of a moving reaction front [15], or some experiments of interfacial electrodeposition [16]. In the case of the Liesegang patterns, it is well known that the distance between rings increases as $t^{1/2}$, whereas in bacterial and electrodeposition it is constant.

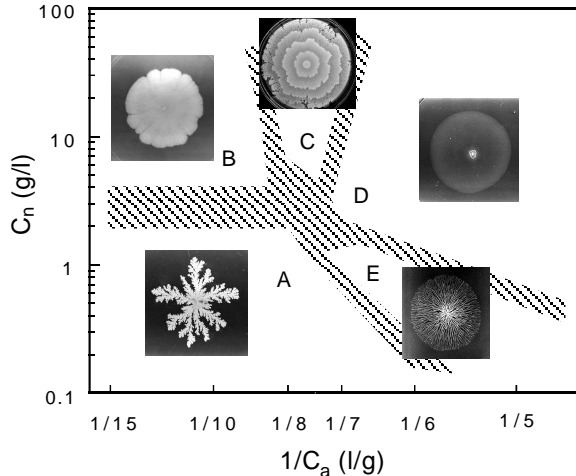

FIG. 1. Morphological diagram of patterns observed in colonies of *Bacilus subtilis* OG-01 as a function of nutrient concentration (C_n) and the hardness of agar surface ($1/C_a$ being C_a the agar concentration). Experiments were performed in a petri dish with a diameter of 88 mm. Taken with permission from [8].

Several models have been proposed to explain the variety of patterns exhibited by *Bacillus subtilis*, as shown in Fig. 1. [2,3,9,17–21]. DLA-like patterns (region A in Fig. 1) have been interpreted [9] as growth controlled by the diffusion of nutrients in the context of the DLA model. Ben-Jacob and co-workers proposed a communicating walkers model to describe some of the morphologies [2,3]. This model reproduces the crossover between regions A and B by coupling random walkers to fields representing the nutrients. DBM-like patterns are also obtained by introducing a chemotactic agent. Other kinds of models are based on reaction-diffusion equations for bacterial density. The Fisher equation [17] can be used for reproducing the homogeneous circular morphology (region D) [18]. Further developments were achieved by introducing new elements to the Fisher model, such as a field for nutrient and nonlinear diffusion coefficients [19,20]. Depending on the new elements introduced, these models reproduce some of the patterns of Fig. 1. However, the ring patterns (region C) have so far eluded a satisfactory

modelization. Although the model suggested in Ref. [20] can generate concentric ring patterns, they are rather different from those observed in experiments [8]. In fact, dynamical cycles of consolidation and growth phases are not found. Finally, we must mention a model proposed by Esipov *et al.* [21] for the study of *Proteus mirabilis* colonies, which introduces a life-time for the differentiated swarmer bacteria. This model reproduces concentric ring patterns but does not explain why no periodicity is observed in other regions of the morphological diagram.

In this paper, we propose a model consisting of two coupled diffusion-reaction equations for bacteria and nutrient concentrations, where the bacterial diffusion coefficient can adopt two different expressions, corresponding to two possible mechanisms of motion. The first is the usual random swimming performed by bacteria in liquid medium. The second is developed by bacteria in response to adverse growth conditions, and depends on their concentration. Bacterial response is modeled as a global variable that can present hysteresis. Our model reproduces the five morphologies observed in the experiments, including the ring patterns.

II. MATHEMATICAL MODEL

We consider a two-dimensional system containing bacteria and nutrients. Both diffuse, while bacteria proliferate by feeding on nutrient. Let us denote by $\bar{b}(\mathbf{r}',\tau)$ the density of bacteria at time τ and spatial position $\mathbf{r}'$, and by $\bar{n}(\mathbf{r}',\tau)$ the concentration of nutrient. Then, $\bar{b}$ and $\bar{n}$ are in general governed by the following equations [17,19]:

$$\frac{\partial \bar{b}}{\partial \tau} = \nabla D_b \nabla \bar{b} + \theta f(\bar{b},\bar{n}),$$

$$\frac{\partial \bar{n}}{\partial \tau} = D_n \nabla^2 \bar{n} - f(\bar{b},\bar{n}). \tag{1}$$

The function $f(\bar{b},\bar{n})$ denotes the consumption term of nutrient by bacteria, and can be described by Michaelis-Menten kinetics [17]

$$f(\bar{b},\bar{n}) = \frac{k\bar{n}\bar{b}}{(1+\gamma'\bar{n})}, \tag{2}$$

where k is the intrinsic consumption rate. For small $\bar{n}$, the consumption rate is approximately linear in $\bar{n}$ and it saturates at the value k/γ' as $\bar{n}$ increases. D_b and D_n are the diffusion coefficients of bacteria and nutrient respectively. We assume that D_n is constant, but D_b can depend on nutrient and bacterium concentrations.

As explained above, experiments show that in adverse conditions, bacteria can adapt themselves in order to improve their motility. In a soft medium and high nutrient concentration (region D of Fig. 1), short bacteria can

2

swim randomly without difficulty, but in an adverse environment (regions A, B, C and E) they need to develop mechanisms to become more motile. For intermediate conditions of semi-solid medium and sufficient nutrient, there are periods of fast growth (migration phase) and slow growth (consolidation phase) that lead to the concentric ring patterns.

The analysis of periodic rings suggests a dynamical scheme with hysteresis that can be outlined in the following way: during the consolidation phase, the population of longer-motile bacteria increases in order to overcome the opposition to the movement. When this population exceeds a certain value, enhanced movement becomes possible and a migration phase begins. Then, however, a progressive decrease in long-bacterial population ensues, until it reaches a minimum at which the "enhanced-movement mechanism" does not work. Then a new consolidation phase begins. Within this scheme, region D corresponds to a case where the maximum value is never reached (and therefore bacteria always move by usual diffusion), whereas in regions A, B and E long-bacterial population does not fall below the minimum (and therefore always moves by the enhanced-movement mechanism). All these ideas can be introduced in our model by means of two basic points:

(a) The diffusion coefficient $D_b(\bar{n}, \bar{b})$ can take two different expressions depending on the long-bacterial population.

(b) The net production of long bacteria depends on the environmental conditions and also on the colony phase of growth.

According to these ideas, we propose the following function for D_b:

$$D_b = D(\bar{d}_1 + \bar{d}_2\bar{b})\bar{n}, \qquad (3)$$

where D depends on the concentration of agar, which is lower for harder medium. To take into account the inhomogeneities of the medium, we introduce a quenched disorder in D, which is written as $D = D_0(1+\xi(\mathbf{r}'))$, $\xi(\mathbf{r}')$ being a random term defined on a square lattice. From now on, D_0 will be referred to as the diffusion parameter.

The first term of Eq. (3) describes the usual diffusion of bacteria in a liquid medium. The second describes the cooperative enhanced-movement mechanism promoted by long bacteria. This second mechanism can be modeled by a diffusion coefficient that depends on the bacterial concentration. We multiply both terms by nutrient concentration to take into account the fact that bacteria are inactive in the region where nutrient has been depleted. This dependence on $\bar{n}$ would not have been necessary if we had considered a "death" term in the equation for $\bar{b}$. The coefficients d_1 and d_2 can adopt two different values (one of them zero) depending on the concentration of the long bacteria, as will be specifed below.

Equations (1) with Eqs. (2)-(3) can be written in a simpler form as

$$\frac{\partial b}{\partial t} = \nabla \left\{ D\left(d_1 + d_2 b\right) n \nabla b \right\} + \frac{nb}{1 + \gamma n},$$
$$(4)$$
$$\frac{\partial n}{\partial t} = \nabla^2 n - \frac{nb}{1 + \gamma n},$$

with

$$\mathbf{r} = \left(\frac{\theta k^2}{D_n}\right)^{1/4} \mathbf{r}', \quad t = k\left(\theta D_n\right)^{1/2}\tau,$$
$$n = \left(\frac{\theta}{D_n}\right)^{1/2}\bar{n}, \quad b = \left(\frac{1}{\theta D_n}\right)^{1/2}\bar{b}, \qquad (5)$$
$$\gamma = \left(\frac{D_n}{\theta}\right)^{1/2}\gamma', \quad d_1 = \left(\frac{1}{\theta D_n}\right)^{1/2}\bar{d}_1, \quad d_2 = \bar{d}_2.$$

At this point, we need to specify how to choose d_1 and d_2 depending on the population of long bacteria. In order to do this, we introduce a global phenomenological quantity $W(t)$ that measures the amount of long bacteria. The evolution of this quantity should have a "creation term" that represents the transformation of short bacteria into long ones, and an "annihilation term" that represents the opposite transformation (septation). It seems reasonable to assume that the creation term is directly dependent on the mean bacterial concentration, and inversely dependent on the level of nutrient (n_0) and on the diffusion parameter (adverse conditions, *i.e.* D_0 and n_0 small, means a faster differentiation process). With regard to the annihilation term, it can adopt two possible values depending on the growth phase. The simplest equation that includes all these considerations can be written as

$$\frac{\partial W}{\partial t} = \lambda \frac{B}{n_0 D_0} - c_i, \qquad (6)$$

where λ is a constant and c_i can have two different values (c_g or c_s, $c_g > c_s$). The quantity B, defined as $B = \sum b^2 / \sum b$, is a measure of the mean concentration of bacteria inside the colony. We introduce the hysteresis previously pointed out by assuming that there are two limit values W_{MAX} and W_{MIN} for which:

when $W \geq W_{MAX}$ then $c_i = c_g$, $d_2 = D_2$, $d_1 = 0$,
$$(7)$$
when $W \leq W_{MIN}$ then $c_i = c_s$, $d_2 = 0$, $d_1 = 1$.

With a suitable choice of parameters λ, c_s and c_g, and by changing only n_0 and D_0, we can obtain colonies that always move with one of the two types of diffusion, or colonies that periodically change from one type to the other. This will occur if $c_s < \lambda B/(n_0 D_0) < c_g$, which will give rise to the ring patterns. Although the bacterial response has been expressed in terms of the population of long-bacteria, other possible kinds of responses admit identical modelization. In this sense, our model is quite general.

III. NUMERICAL RESULTS

We have numerically integrated Eqs. (4) with (6)-(7) in a square lattice of lateral size $L = 600$ using a 4-th order Runge-Kutta's method with mesh-size $\Delta x = 0.5$ and time step $\Delta t = 0.005$. The system was initially prepared by assigning to each point a nutrient concentration $n(\mathbf{r}, 0) = n_0 + \eta(\mathbf{r}, 0)$, η being a uniform random number in the interval $(-0.1, 0.1)$, and a bacterial concentration $b(\mathbf{r}, 0) = 0$, except in a small central square where $b(\mathbf{r}, 0) = b_0$. The random term of the diffusion, $\xi(\mathbf{r})$, takes a different and uncorrelated value in each box of side $4\Delta x$. The random values are assumed to be uniformly distributed in the interval $(-\epsilon, \epsilon)$. The box size and the intensity ϵ do not essentially affect the results.

In all our simulations, we used the parameters $b_0 = 0.7$, $\gamma = 0.5$, $D_2 = 30$, $\epsilon = 0.4$, $\lambda = 0.18$, $c_g = 2$, $c_s = 1.6$, $W_{MAX} = 3$ and $W_{MIN} = 2$. We reproduce the different morphologies observed in experiments by changing the values of the initial concentration of nutrients n_0 and the softness of the media, related to D_0.

(a)   (b)

FIG. 2. Bacterial colonies (top) and nutrient patterns (bottom) for a fixed value of $D_0 = 0.01$ and two values of initial nutrient: $n_0 = 1(a)$ and $n_0 = 5(b)$. They correspond to times $t = 2500$ and 75 respectively.

In Figs. 2-3 we present the results obtained for $D_0 = 0.005$ and different values of n_0. By increasing n_0 we reproduce the crossover between regions A and B of Fig. 1, from DLA-like patterns (Fig. 2(a)) to a dense rough structure similar to that found with an Eden model (Fig.

2(b)). All of them correspond to a situation in which, due to the small value of D_0, the creation term of Eq. (6) is greater than c_g, except at the very beginning. The response W can never decrease below the value W_{MIN}, and therefore the colony will always grow with the enhanced-movement mechanism. In spite of this cooperative mechanism, and because of the hardness of the medium, the effective diffusion $D_0 D_2 bn$ is still small. The growth is mostly due to reproduction by feeding on the nutrient. For low level of nutrient, i.e. small n_0, the colony growth is limited by the diffusion of these nutrients. It develops branches, which are thicker as n_0 increases. The prototype model that reproduces this kind of structure is the diffusion-limited aggregation (DLA) [12], which is known to form a fractal pattern with a fractal dimension of $d_F = 1.71$ [1,22]. Experiments performed by Matsushita et al. [9] in region A of Fig.1 also show a fractal growth with dimension $d_F = 1.73$ [9]. We have analyzed the fractal nature of the patterns obtained with our model, for $D_0 = 0.005$ and several values of the initial nutrient, from $n_0 = 1$ (DLA-like) to $n_0 = 5$ (rough structure). We have calculated their fractal dimensions by using the box-counting method [1,22]. In Fig. 3 we show, in a log-log plot, the number N of boxes of size e that contains any part of the pattern, versus the size of the boxes. The slopes of the lines represent the fractal dimensions. We observe that the cases that correspond to low nutrient have a fractal dimension of about $d_F = 1.73$, showing good agreement with experiments. On the other hand, there is an abrupt change between these patterns and those that are not fractal ($d_F = 1$). These last cases can be analyzed in terms of the roughness of their interfaces.

FIG. 3. Fractal dimensions determined by the box–counting method, for $D_0 = 0.01$ and $n_0 = 1(\bigcirc), 2(\diamond), 3(\square)$ and $5(\triangle)$. Two lines of slopes 1 and 1.73 are also plotted for comparison with experiments.

It is well known that Eden structures are not themselves fractal, but their surfaces exhibit a self-affine scaling [22,23]. This implies that, for a long enough time, the width of the rough interface σ scales with an exponent α as a function of the length of the interface l ($\sigma \sim l^{\alpha}$). The roughness exponent for the Eden model is $\alpha = 0.5$. Vicsek et al. [13] analyzed experimental data corresponding to the region B of Fig. 1. They concluded that these colony surfaces are self-affine with a roughness exponent $\alpha = 0.74$. We have checked this point for our dense rough pattern (Fig. 2(b)) by measuring the width σ for intervals of interface of length l. The results, as a function of l, are presented in Fig. 4. In order to avoid additional effects derived from the radial growth of the colony, we have also performed a complementary simulation for the same parameters as Fig. 2(b) but with a strip geometry. To do this, we have used a rectangular lattice of horizontal lateral size $L_x = 600$, with periodic boundary conditions in x direction, and taken as an initial condition for bacteria a horizontal line of length L_x. The results for this case are also plotted in Fig. 4. For both circular and strip cases, we observe analogous behavior to that observed in experiments [13]. Our results show a linear region with a slope compatible with the experimental value $\alpha = 0.74$.

FIG. 4. Width of the rough interface as a function of the length of the interval in which it is measured. They correspond to the pattern of Fig. 2(b) ($\square$) and to a case with the same parameters but with strip geometry ($\triangle$). A line of slope 0.74 is also plotted for comparison with experimental results.

With the aim of reproducing other morphologies of Fig. 1, we now keep the initial nutrient fixed at the value $n_0 = 1$ and increase the diffusion parameter D_0. Results are shown in Fig. 5(a)-(b). We observe a crossover from the DLA-like structure (Fig. 2(a)) to a dense branching morphology analogous to that represented in region E of Fig. 1.

In Fig. 5(c)-(d), we present two snapshots obtained for a fixed value of the initial nutrient $n_0 = 5$. They show how different kinds of patterns are obtained when D_0 is increased: from the dense rough structure (Fig. 2(b)), to concentric rings (Fig. 5(c)) and homogeneous disk (Fig. 5(d)). They correspond to the regions B, C and D respectively. Homogeneous disks are obtained when D_0 and n_0 are so high that the creation term of Eq. (6) is always smaller than c_s. This means that the value W_{MAX}, above which the enhanced-movement mechanism begins, is never reached, and bacteria move with the usual diffusion coefficient $D_0 n$.

FIG. 5. Patterns obtained for $n_0 = 1$ with $D_0 = 0.05(a)$ and $0.1(b)$ and for $n_0 = 5$ with $D_0 = 0.1(c)$ and $2(d)$. They correspond to times $t = 500, 300, 50$ and 25 respectively.

Ring patterns correspond to a narrow region of parameters D_0 and n_0 for which the creation term of Eq. (6) takes a value between c_s and c_g. As explained in Section II, this leads to dynamics in which bacteria move alternatively by usual diffusion $D_0 n$ (consolidation phase) or by the enhanced-movement mechanism $D_0 D_2 bn$ (migration phase). The two phases are clearly manifested in Fig. 6(a), where we represent the radius of the colony as a function of time. The pattern of concentric rings is a consequence of this dynamic behavior. In Fig.6(b) we plot the radial density profile, circularly-averaged, corresponding to the ring pattern shown in Fig. 5(c). The maxima are formed in the positions where a consolidation phase began. To illustrate this point, we have pointed out in Fig. 6 the positions corresponding to the colony radius

at the beginning of each consolidation phase.

FIG. 6. (a) Time evolution of the colony radius, for parameters $D_0 = 0.1$ and $n_0 = 5$; (b) Radial density profile corresponding to time $t = 50$ (pattern of Fig. 5(c)). The positions where each consolidation phase started are pointed out.

Numerically, our model also reproduces the experimentally observed robustness of the growth-plus-consolidation period, which is barely dependent on changes in either nutrient or agar concentrations over a wide range. For high enough n_0, the value of the global quantity B approaches n_0. In this limit, as can be derived from Eq. (6) the period is given by

$$T = D_0(W_{MAX} - W_{MIN}) \left(\frac{1}{\lambda - D_0 c_s} - \frac{1}{\lambda - D_0 c_g} \right), \quad (8)$$

which does not depend on n_0. Moreover, as a function of D_0, the period also maintains a rather constant value within a certain range (determined by parameters λ, c_g and c_s) to increase sharply in the boundaries of the ring patterns region ($D_0 \longrightarrow \lambda/c_s$, $D_0 \longrightarrow \lambda/c_g$). For equal period, the width of the rings increases with n_0.

IV. CONCLUSIONS

We have proposed a reaction-diffusion model for the study of bacterial colony growth on agar plates, which consists of two coupled equations for nutrient and bacterial concentrations. The most important feature, which introduces differences from previous models, is the fact that here we consider two mechanisms for the bacterial movement: the random swimming in a liquid medium, and a cooperative enhanced movement developed by bacteria when the growth conditions are adverse. The two mechanisms are introduced in our model by means of a diffusion term with two different expressions which depend on the bacterial response to the environmental conditions. This response is modeled as a global variable that presents hysteresis depending on the conditions of the medium. The inhomogeneities of the agar plate have been taken into account as a quenched disorder in the diffusion parameter.

We have shown that, simply by changing the parameters related to the hardness of the medium and the initial nutrient, our model reproduces all the patterns obtained experimentally with the bacterium *Bacillus subtilis*: DLA-like, dense-rough disk, DBM-like, ring patterns and homogeneous disk. We have calculated the fractal dimension of the DLA-like structures and the roughness exponent of the rough disk surface, obtaining results in good agreement with experiments. The ring patterns have been obtained for intermediate values of agar and high nutrient. In this region, the bacterial response presents hysteresis and the two mechanisms of motion work alternatively, leading to cycles of migration and consolidation phases. The duration of these cycles is roughly constant for different values of nutrient and agar concentration over a wide range. This periodical dynamics generates patterns of concentric rings.

In summary, the model proposed satisfactorily reproduces the whole experimental morphological diagram. It represents a first attempt at describing the response of bacteria to adverse growth conditions and, in certain conditions, their ability to improve their motility. Further refinements could be made. The bacterial response, here described as a global variable $W(t)$, could be considered in a more realistic way by introducing a coupling term in a local version of Eq. (6) for a field $W(\mathbf{r}, t)$. However, preliminar studies with such a model [24] shows the same essential features previously described.
